What is Volatility?

- ▶ Volatility is a measure of price variability over some period of time
- ▶ Typically described by the standard deviation σ of the return series $\{X_t\}$
- ▶ Volatility is peculiar in that we know it exists, but in some sense we can't really measure it
- ▶ Bachelier (1900) showed that $\{X_t\} \sim \text{iid. } N(0, 1)$, but this is only good for a first order approximation

Naive Measure - Realized Volatility

Stylized Facts

Further analysis of $\{X_t\}$ reveals other kinds of structure that cannot be explained by the gaussian assumption.

In particular, the return series displays the following distinctive behavior:

1. $\{X_t\}$ is heavy-tailed, much more so than the Gaussian white noise
2. Although $\{X_t\}$ is uncorrelated, the series $\{X_t^2\}$ is highly correlated
3. The changes in $\{X_t\}$ tend to be clustered, large changes tend to be followed by large changes and vice v
4. Effects are asymmetric, bad news results in larger downward price moves than positive news does to upward price moves

GARCH

The Generalized ARCH (GARCH) model of Bollerslev (1986) and its variants are extremely popular (albeit imperfect) methods to model volatility.

GARCH(p,q) model can be expressed as:

$$X_t = \sigma_t \varepsilon_t, \quad \varepsilon_t \sim N(0, 1)$$

where

$$\sigma_t^2 = \alpha_0 + \sum_{i=1}^p \beta_i \sigma_{t-i}^2 + \sum_{j=1}^q \alpha_j X_{t-j}^2$$

For the purposes of this talk, we'll focus on GARCH(1,1) models where $\sigma_t^2 = \alpha_0 + \beta_1 \sigma_{t-1}^2 + \alpha_1 X_{t-1}^2$

NoVaS Transformation (Politis 2007)

The NoVaS Transformation is defined as

$$W_{t,a} = \frac{X_t}{\sqrt{\alpha s_{t-1}^2 + a_0 X_t^2 + \sum_{i=1}^p a_i X_{t-i}^2}}$$

for $t = p + 1, p + 2, \dots, n$

It is a clever extension of the ARCH model where we include the value X_t in order to “studentize” the returns.

The order p and the vector of nonnegative parameters $(\alpha, a_0, \dots, a_p)$ are chosen by the practitioner with the twin goals of normalization and variance-stabilization.

Algorithm for Simple NoVaS:

- ▶ Let $\alpha = 0$ and $a_i = \frac{1}{p+1}$ for all $0 \leq i \leq p$
- ▶ Pick p such that $|KURT_n(W_{t,p}^S)| \approx 3$

Volatility Prediction

- ▶ Forecasts of volatility are important when assessing and managing the risks of portfolios
- ▶ We focus on the problem of one-step ahead X_{t+1} prediction based on the observed past
- ▶ For our purposes, volatility prediction = predicting X_{t+1}^2
- ▶ Even though X_{t+1}^2 is a noisy proxy for $\mathbb{E}(X_{t+1}^2|\mathfrak{F}_n)$, we'll see that in under some conditions NoVaS allows us to predict the latter
- ▶ Assuming more realistically that financial returns are locally stationary, we use a rolling window size of 250 days to calculate our forecasts

Which Loss Function? L_1 or L_2 ?

- ▶ To assess the accuracy of forecasts, we need to decide on a loss function to use
- ▶ The MSE is most commonly used, however note that $\mathbb{E}(Y_{n+1}^2 - \widehat{Y_{n+1}^2})^2$ is essentially a fourth moment
- ▶ Thus the unconditional MSE is infinite if the returns process has infinite kurtosis!
- ▶ We find that this indeed the case and so focus on the Mean Absolute Deviation (MAD) loss function
- ▶ Under the objective of L_1 -optimal prediction, the optimal predictor is $\text{Median}(X_{n+1}^2 | \mathfrak{F}_n)$

Empirical Kurtosis Plot S&P500

Empirical Kurtosis Plot BTC

GARCH(1,1) Prediction

Recall the GARCH(1,1) model can be expressed as:

$$X_t = \sigma_t \varepsilon_t, \quad \varepsilon_t \sim N(0, 1)$$

where $\sigma_t^2 = \alpha_0 + \beta_1 \sigma_{t-1}^2 + \alpha_1 X_{t-1}^2$

To perform one-step ahead prediction with GARCH(1,1) we:

- ▶ Estimate the parameters α_0, β_1 and α_1 using MLE
- ▶ Let $a = \frac{\alpha_0}{1-\beta_1}$ and $a_i = \alpha_1 \beta_1^{i-1}$ for $i = 1, 2, \dots$

Then the L_1 -optimal GARCH(1,1) predictor of X_{n+1}^2 is given by

$$\text{Median}(X_{n+1}^2 | \mathfrak{F}_n) = (a + \sum_{i=1}^p a_i X_{n+1-i}^2) \text{Median}(\varepsilon_{n+1}^2)$$

Special Case: Uncorrelated NoVaS Series $W_{t,a}$

NoVaS Prediction in Special Case

From the ACF plot on the previous slide, we can conclude that the NoVaS transformed series $\{W_{t,a}\}$ of the S&P500 returns appears to be uncorrelated.

As a result we can predict X_{n+1}^2 (under L_1 loss) by

$$X_{n+1}^2 = \widehat{\mu}_2 A_n^2$$

where

$$\widehat{\mu}_2 = \text{median}\left\{\frac{W_{t,a}^2}{1 - a_0 W_{t,a}^2}; t = p+1, p+2, \dots, n\right\}$$

and

$$A_n^2 = \alpha s_{t-1}^2 + \sum_{i=1}^p a_i X_{t+1-i}^2$$

Bootstrap Prediction Intervals

In addition to calculating point estimates, we calculate prediction intervals.

Below is an outline of the procedure used for NoVaS (GARCH is almost identical):

1. Use Simple NoVaS to obtain transformation $\{W_{t,a}\}$ and fitted parameter p
2. Calculate $\widehat{g(X_{n+1})}$ the point predictor of $g(X_{n+1})$
3. Resample randomly (with replacement) the transformed variables $\{W_{t,a}\}$ for $t = p + 1, \dots, n$ to create the pseudo-data $W_{p+1}^*, \dots, W_{n-1}^*, W_n^*$ and W_{n+1}^*
4. Let $(X_1^*, \dots, X_p^*)' = (X_{1+l}^*, \dots, X_{p+l}^*)'$ where $l \sim U\{0, n - p\}$

Bootstrap Prediction Intervals

5. Generate the bootstrap pseudo-data Y_t^* for $t = p + 1, \dots, n$
6. Based on the bootstrap data Y_1^*, \dots, Y_n^* re-estimate the NoVaS transformation, then calculate the bootstrap predictor $\widehat{g}(Y_{n+1}^*)$
7. Calculate the bootstrap future value Y_{n+1}^* and the bootstrap root: $g(Y_{n+1}^*) - \widehat{g}(Y_{n+1}^*)$
8. Repeat steps 3-7 B times - the B bootstrap root replicates are collected in the form of an empirical distribution whose α -quantile is denoted $q(\alpha)$
9. The $(1 - \alpha)100\%$ equal-tailed prediction interval for $g(Y_{n+1})$ is given by

$$[\widehat{g}(Y_{n+1}) + q(\alpha/2), \widehat{g}(Y_{n+1}) + q(1 - \alpha/2)]$$

4. A Simple Volatility Trading Strategy

Estimating the volatility $\mathbb{E}(X_{n+1}^2|\mathfrak{F}_n)$

In order to implement our volatility trading strategy we'd ideally like an estimate of $\mathbb{E}(X_{n+1}^2|\mathfrak{F}_n)$.

Fortunately, it is straightforward to do so under the case were the NoVaS series $W_{t,a}$ is uncorrelated and independent.

$$\mathbb{E}(Y_{n+1}^2|\mathfrak{F}_n) = A_n^2 \mathbb{E}\left(\frac{W_{t,a}^2}{1 - a_0 W_{t,a}^2}\right)$$

a natural estimate is therefore

$$\frac{A_n^2}{n-p} \sum_{t=p+1}^n \left(\frac{W_{t,a}^2}{1 - a_0 W_{t,a}^2} \right)$$

Volatility Trading Strategy (Ahmad & Wilmott 2005)

Relevant Definitions:

- ▶ Implied Volatility (IV) - value calculated from an option price
- ▶ VIX - popular index which is a measure of the stock market's expectation volatility implied by S&P500 index options
- ▶ $VIX(t) = IV(t)$ current implied volatility
- ▶ VXX - ETN that (imperfectly) tracks VIX index
- ▶ $RV(t+1)$ - is the GARCH or NoVaS predicted realized volatility for next period
- ▶ Expect $RV(t+1)$ to be better predictor of $VIX(t+1)$ than $VIX(t)$

Strategy:

If $RV(t+1) - VIX(t) > 0$ then BUY VXX. Vice Versa
